**ABSTRACT.** Acknowledged and justified is the recognition of remote sensing as a powerful tool in land cover/land use monitoring for a large number of purposes ranging from agricultural practices to global ecology and environment protection. Data collected and information created from Earth observations constitute critical inputs to the sustainable management of the Earth – providing evidence for informed decision-making. However, policies on the environment often suffer by having to rely on information that is fragmentary and of uneven quality and value despite of the considerable progress that has been made in space-borne observation systems and information technologies. Currently, the remote sensing community is recognizing again, in a more complex and systematic way, the indispensable necessity of ground-truth information in support of satellite Earth observation missions. In order the remote sensing techniques to be widely transferred to operative applications, data accuracy and information reliability is critical. Algorithms and quantitative models for estimating various land surface variables from remotely sensed observations need to be validated using geo-reference data. Supporting and raising the capacity of remote sensing investigations encompasses the implementation of a wide range of information sources, making full use of ground-based in-situ monitoring as well as of airborne surveys and space-based observations. In this context the paper presents a vision on the objectives, the infrastructure and the functioning of in-situ networks for data acquisition on target selected test-sites with the aim to enhance remote sensing scientific and modelling capacities and to meet the need for multidisciplinary research and multipurpose data application relying both on technology developments and data accuracy. The paper aims also at rising the interest in international networking and collaboration.

### **НАЗЕМЕН КОМПЛЕКС ИЗСЛЕДВАНИЯ ПРИ КОСМИЧЕСКИ НАБЛЮДЕНИЯ**

**РЕЗЮМЕ.** В последните години има все повече необходимост от наземна информация при провеждането на космически наблюдения на Земята. Това засяга множества задачи от най-малкия регионален мащаб при селското стопанство и минната дейност до глобалните промени в околната среда. Алгоритмите и количествените модели за оценка на промените на земната повърхнасто по дистанционни данни са основен работен инструмент. Тази работа представя един комплекс със съответните обекти на наблюдение, инфраструктура и функциониране на наземна мрежа за получаване на данни на избрани полигони (test-sites) с цел повишаване на точността на крайните данни.

### **Introduction**

The challenges posed by the increasing natural and man-made pressures on the environment and its resources require efficient and coordinated research at different levels. Dealing with the consequences of the anthropogenic impact on the environment and the ecological balance requires more informed policies. The same refers to geo-hazards such as floods, landslides, wildfires, pollution and etc. This implies better understanding of the events and improved assessment and forecasting to mitigate risks. A multidisciplinary and integrated approach is needed in order to advance our knowledge on the interactions between the climate, biosphere, ecosystems and human activities. This will help to develop new environmental technologies, tools and services for sustainable management of resources.

Acknowledged and justified is the recognition of remote sensing as a powerful tool in land use/land cover monitoring for a large number of purposes ranging from agricultural practices to global ecology and environment protection. Data collected

and information created from Earth observations constitute critical inputs to the sustainable management of the Earth – providing evidence for informed decision-making. However, a better data provision is needed to fill existing gaps. Policies on the environment often suffer by having to rely on information that is fragmentary and of uneven quality and value. This is despite the fact that over the last years considerable progress has been made in space-borne devices and observation systems.

Ecosystem assessment and related ecological issues are one of the most important areas in using remote sensing data. Land cover dynamics is strongly influenced by a great number of factors, generating the need for adequate mapping and monitoring tools. As a consequence, robust and sophisticated analysis methods are required for efficient data handling and accurate information extraction adopted to the rapid advances in sensor technologies. Besides, multi-temporal and multi-sensor approaches are becoming more and more important not only for change detection but also for the development of

more detailed classification and state assessment methods. In the study of land covers the information requirements can be effectively met by using conventional (terrestrial) and modern remote sensing techniques. Often remote sensing data alone do only perform a part of the job since comprehensive end-user products are a result of the combination of remotely sensed data coupled with ground survey and modeling. Data accuracy, data processing, and the creation of customer specific and dedicated products are keys for a breakthrough of remote sensing applications. Data reliability is essential as well.

Currently, the remote sensing community is recognizing again, in a more complex and systematic way, the indispensable necessity of ground-truth information in support of satellite Earth observation missions. In order the remote sensing techniques to be widely transferred to operative applications, data quality and retrieved information reliability are critical. Algorithms and quantitative models for estimating various land surface variables from remotely sensed observations need to be validated using ground-truth data. Supporting and raising the capacity of remote sensing investigations encompasses the implementation of a wide range of information sources, making full use of in-situ ground-based and airborne surveys as well as of space-based monitoring.

In this context the paper presents a vision on the objectives and functioning of in-situ infrastructure for data acquisition on target selected and representative of different ecosystems and environmental conditions test-sites. It outlines the most necessary steps towards the constitution of an efficient system for information support in the field of Earth resources and ecology. The development of an integrated in-situ and remote sensing information system responds to the needs for coordinated multi-disciplinary data acquisition, data integration and multi-use in monitoring the state of the environment, including air, water, soil, natural landscape and farmlands.

### In-situ support – closing the gaps

Spatial information (any data with reference to a specific location or geographical area) plays a special role in environment monitoring because it allows information to be integrated from a variety of sources and disciplines for a variety of uses. However, the widespread use of spatial information is still not a routine. The main problems relate to data gaps, incompatible data sets and services due e.g. to varying data needs, standards, undefined quality and barriers to sharing, accessing and using of data. Some technical and economic characteristics of spatial information make the problems particularly acute. Undoubtedly is, however, the awareness that quality information is needed in order to understand the complexity of ever-increasing human activity and that such information should be collected and used in an operational mode.

Remote sensing is an important source of information for a large number of Earth sciences and application fields. Data acquisition technologies and information extraction methods are pushed to give shift to user-oriented approaches where quantitative and reliable assessments, trend evaluations and forecasts are demanded. To achieve this, it is necessary to make full use of data collected from space-borne, airborne and

field observation systems (the latter two composing the in-situ system). The way is to optimize the infrastructure for data acquisition, efficient processing, integration and use. The optimization includes adequate instrumentation and better timing and coordination in information collecting and management. Validation of data processing and retrieval algorithms has an essential importance as well. In this context, the in-situ support is indispensable because: ● Despite advances made in sensor technology, data evaluation techniques and information networks, the production of information remains often below its full potential to provide benefits for the users; ● Not all problems related to data acquisition, combining and integration from different sources have been addressed; ● Initiatives to share data between users and applications are not enough; ● Without a clearly designed and shared multi-use infrastructure that encompasses ground-based, airborne and space tools, the implementation of policies affecting the environment, natural resources and land use will be hampered by the barriers to gathering and exploiting cross-domain data; ● The synergy approach is a highlight of today's information technologies and responds to the need to integrate environmental considerations in view of promoting sustainable development; ● Calibration of the implemented systems and validation of the operational tools (models, information extraction algorithms) and information products through geo-referencing and ground-truth data gathering on test-sites are required to enhance data accuracy and reliability in order to provide the maximum added value. Thus, the provision of information products relies both on the space and in-situ components that capture the required data. Data sharing and integration from different levels (ground-based and remote sensing), sources and at different scales are needed to increase the potential of the observations and to ensure cross-level and cross-thematic consistency of the acquired data.

All these come to clarify that for the production of high-quality and timely information, an adequate in-situ support is required enabling data demand definition, acquisition, processing and use. Developing the in-situ component in environment and land cover monitoring is an essential step to the creation of the necessary integrated space-terrestrial information system incorporating ground-based and remote sensing means for spatial data collection, handling and dissemination. In this way the overall continuity, comparability and integration of space and in-situ data, modeling activities and interoperability of the systems will be strengthened. Since much of the data is to be underpinned by "multi-purpose" information, special emphasis should be put on coordinated data acquisition, evaluation of different user data needs and access to information products. Remote sensing information technologies have passed different stages in their development from sensor design to observation missions and data application. Views have changed during these stages on the importance of the various links of the information chain. Today it is unambiguously recognized that the in-situ component (encompassing field and airborne observations) is not only an integral part but the backbone of a spatial data information system and that in conjunction with the space component forms a common environmental info-structure. To adequately obtain and deploy information, substantial improvement is required in in-situ surveys, observing systems and networks together with the development of GMES-oriented information services.

## Integrated ground-based and remote sensing information system

Because of its dispersed nature, it is more difficult to capture the full complexity of the in-situ information system than the space segment. The ground-based component relates to data collected by: (i) networks of sensors deployed on land, sea, water and in the atmosphere aimed at measuring and providing a complete description of the investigated object; (ii) surveys aimed at collecting socio-economic data, land cover and land-use data, geological, soil and bio-diversity information and other geographical data (such as for example elevation, administrative boundaries, etc). In-situ studies play a major role for the elaboration of information extraction methods and validation of algorithms and models. Geolocation of satellite imagery is needed because only if the navigation on ground does sufficiently coincide with the target parameters measured from space the data are useful. Remote sensing devices measure different spectral characteristics of land covers (reflectance, emittance, fluorescence) in a wide range of electromagnetic wavelengths (optical, thermal, radio). The spectral response of land covers is associated with and depends on the target type (vegetation, soils, rocks, water) and its biophysical and chemical properties, physiological and morphological state (biomass, leaf area index, chlorophyll, water content, mineral composition, organic matter and etc.). Ground-truth data allows quantitative relationships to be established and spectral-biophysical modeling to be performed which lies at the root of using remotely sensed data.

For instance, many of the applications of remote sensing rely on multispectral data in the visible and near infrared band where the radiometric sensitivity of the optical instruments is sufficient to measure small changes in target reflectance. Surface reflectance retrieval from imaging data is needed for quantitative information extraction. On the other hand, image data have to be expressed in reflectance values in order to allow comparisons with field or laboratory measurements and to be used in inversed models for target parameters retrieval. In order to calculate surface reflectance from remotely measured radiance, radiative transfer models are elaborated for removal of the scattering and gaseous absorption effects of the atmosphere. Comparison and verification of the retrieved land cover reflectance by ground-based reflectance measurements are essential for accurate information content extraction from remotely sensed data. In order reliable predictive equations of land cover parameters to be obtained from spectral data, the predictive ability of the established relationships has to be verified through ground-based measurements, the latter serving also for correction of the atmospheric effects on remotely sensed data. Besides, remote sensing multispectral and hyperspectral sensors have different spectral band-widths and wavelength position. Geo-referencing and ground truthing by in-situ data from test-sites is essential for calibration purposes (ground truth spectral characterization of reference targets, atmospheric corrections, data comparability and verification) and analysis of remotely sensed information. In-situ field and airborne measurements are necessary to check the performance of remote sensing devices through evaluation of data quality (spectral sensitivity, accuracy, signal to noise ratio, signal variations, etc.), and for producing geometrically and radiometrically corrected datasets. Thus spectral data from field devices are needed to elaborate models and perform adequate image analyses and

thematic interpretation of remotely sensed data. The in-situ obtained data are needed to develop land cover classification and state assessment tools basing on their spectral features as well as to perform feasibility studies on extrapolating the information over other similar objects. Some preliminary methodological issues are also essential, such as the timing of data collection, spatial and temporal scale of the measurement, viewing and illumination geometry, ancillary datasets and etc.

All this undoubtedly identifies the necessity of in-situ ground-based and airborne measurements which serve as reference datasets and support satellite data and imagery in terms of: spectroradiometric calibration of remote sensing instruments; radiometric data corrections for the atmospheric effects; transferring image data to target spectral response; referencing remotely sensed data to ground-truth spectral characteristics; enhancement of data accuracy; elaboration of data processing algorithms; integration and fusion of data from different sources and levels (platforms); development of models describing land cover state, trends, forecasts; ground-truth feedbacks and methods for validation of spectral-biophysical models; verification of information extraction techniques.

The integrated information infrastructure consists of distributed and interoperable facilities brought together into a coordinated system oriented towards multiple data use. Encompassing a wide range of information sources and making full use of space and in-situ (ground-based and airborne) monitoring capacities, it includes the following functionalities: data acquisition by a complex of terrestrial and remote sensing equipment; data processing; data verification and validation of algorithms for data analysis through terrestrial investigations on test-sites (ground-truthing); data integration from different sources and transformation into information products (maps, models, etc.). Data storage, cataloguing, access and sharing between users should be enabled as well. The following principles and cross topics contribute to optimizing the overall process in terms of effort and effectiveness: develop synergies; ensure compatibility between ground-based and remote sensing systems; data fusion from multiple sources, data assimilation and data integrity; validation of data acquisition technology and data processing algorithms; verification of the existing and future research results.

In the Figure below, the basic infrastructural segments, components and elements of an integrated terrestrial and remote sensing information system are shown. They are distinguished according to their nature and the function they perform. The ground-based segment includes laboratory and field studies, the in-situ component encompasses additionally airborne surveys. Data Acquisition, Data Processing and Information Production elements refer both to ground-based and remote sensing systems. The in-situ component has the following data acquisition elements: test-sites used for geo-referencing, as well as for calibration and validation needs; spectroradiometric and other sensors for data acquisition; wireless networks for data collecting, storage and transfer; mobile station for the equipment; airborne platforms for remote sensing surveys.

Test-sites are thematically (target) selected territories to represent various ecosystems and landscapes (natural vegetation, forests, agricultural lands, soil types, geological objects) with different land-use, land management and degree of anthropogenic pressure. These test-sites are monitored at regular or requested intervals during the year using a mobile station equipped with a field data acquisition complex. Integral parts of this complex are devices for contact and remote sensing measurements of different physical and chemical parameters such as spectral features (reflectance, absorption, transmittance, fluorescence, etc.), bioparameters (leaf areas index, chlorophyll content, etc.), soil humidity and organic matter, temperature, wind speed, solar irradiance, PAR and etc. Test-sites are thoroughly explored by means of contact field measurements using both destructive and non-destructive methods, and by in-situ (comprising ground-based and airborne) remote sensing techniques. Laboratory analyses are performed using dedicated methodologies and expertise.

The in-situ infrastructure more readily allows a 'build-as-you-need' approach retaining a modular open system that can easily accommodate new elements. Relevant to the latter is the special attention paid to the development and the implementation of field-based networks. Wireless sensor networks and wireless local area networks are most advanced monitoring tools. The survey areas (environment, land covers) that are data intensive need high-performance networks that enable the gathering, aggregation and transfer of data from geographically distributed "autonomous" resources. The architecture progressively evolves from a set of unconnected networks to a fully integrated network, incorporating stand-alone data and information, the selection and aggregation of information from heterogeneous sources and the translation of data in real time. This, in turn, enhances the sharing of environmental information across sites and regions. To maintain coherence between various data sources is an essential emphasis in study activities on test-sites. Measuring environmental variables at appropriate temporal and spatial scales remains an important challenge in ecological research. New developments in wireless sensors and sensor networks will revolutionize the ability to study ecological systems at relevant scales. Sensor networks can analyze and manipulate the data they collect, thereby moving data processing from the end user to the sensor network itself. Such embedded processing will allow sensor networks to perform data analysis procedures, identify outlier data, alter sampling regimes, and

ultimately control experimental infrastructure. A wireless sensor network is an integral component in the infrastructure of an end-to-end information system that transforms raw measurements to scientifically significant data and results. This end-to-end system includes calibration, interface with external data sources (e.g. for measuring agro-meteorological parameters), databases, web-services interfaces, analysis, and visualization tools. Wireless technology used to communicate information from one point to another, can be applied to various electronic devices. Although wireless technologies have been used in specific applications for decades, wireless networks have recently become much more widespread due to better technology and lower prices. Wireless networking offers various advantages over wired connections, including mobility, connectivity, adaptability, and ease of use in locations that prohibit wiring. The work within this information system element covers various aspects of wireless technology, but focuses on improving network performance (network speed, collecting and transmitting capacity), on examining mobility management, energy concerns, spatial diversity and multiuse. Specific applications include wireless sensor networks. A part of the instrumentation is a short range (up to 300 m) independent radio network to service up to 20 different devices from one central point. This central point works in two modes: autonomous (all devices are served at specified time interval and all data are stored) and user-oriented (only some of the devices provide data, but at shorter intervals).

These various instruments and systems need to be configured so that they can exchange information with one another and provide the integrated data and information products that decision makers need. The capacity of ground-based infrastructures to offer reference information and ground-truth data for calibration and validation purposes is critical in environment monitoring. The optimal combination of remote sensing airborne and space systems with terrestrial infrastructures, as well as the integration of multi-source data, creates further application perspectives. This combination comprises target and process dedicated surveys on test-sites, remote sensing and field data acquisition, data fusion from multiple sources, modeling and validation activities. The performance on test-sites of joint ground-based campaigns, airborne surveys and space observations addresses the following main issues: ✓ standards, sensor calibration and atmospheric correction; ✓ multi-platform sensing and sensor networking; ✓ system integration and interoperability; ✓ processing of multi-source and multi-temporal data; ✓ data fusion and information extraction; ✓ quality of spatio-temporal data and validation of models; ✓ remote sensing data verification. The provision of reliable multi-use information through a wide range of information sources and making full use of an appropriate ground-based and airborne in-situ monitoring infrastructure results in improved change detection tools and prediction capabilities.

## Conclusions

Earth monitoring is at a turning point world wide. It is by now well accepted that the proper monitoring of our planet will require the use of both in-situ and remote sensing techniques. While these approaches are operationally very different, they have each an essential role to play in any serious plan to monitor a site, region, country, or the Earth as a whole. Space and in-situ observing systems constitute significant

contributions to environmental assessment, agriculture, water resources, risk mitigation and other domains. The way to strengthen the Earth observation capacity is linking space observations with ground-based monitoring. Linking space observations with ground based monitoring results in reliable data acquisition and enhanced information production techniques.

In combining, integration and joint use of ground and remote sensing data, special attention is to be paid to the development, subsequent upgrading and expanding of the in-situ component. It should be outlined that aiming at optimal combination of terrestrial and space-based infrastructures, as well as at integration and dissemination of data and services will create further interdisciplinary and multi-application perspectives. Putting emphasis on the integration of terrestrial and airborne data with space monitoring will increase the efficiency and information value of research, will develop synergy and enable the validation of end-to-end information products which is an issue of prior importance concerning data reliability. Combining the broad spatial coverage that is one of the great advantages of satellites with the precision of in-situ instruments located in the ocean or on land. This will lead to: enhancement of monitoring technologies (including advanced in-situ sensors); improvement of interoperability and linkage between space observing systems and other data sources; ensuring the compatibility of different types of data; enhancement of modeling capacities; improvement of methods for information retrieval; strengthening the capacity for analysis, forecasting, planning and decision support.

The establishment of an appropriate in-situ network for airborne and ground-truth data gathering, calibration, validating and enhancing space-based observations of ecosystem properties in both terrestrial and aquatic ecosystems supports remote sensing surveys and serve for raising data quality and reliability. It also sets up the path to better coordination and expansion of a network of land, ocean and coastal reference stations for monitoring ecosystem properties (such as carbon, nitrogen, phosphorus, and iron fluxes), including change detection, and to the development of a general strategy for the implementation of advanced information technologies, multi-source data collecting and multi-purpose data use. All this qualifies the in-situ infrastructure as a pillar of the remote sensing surveys and services contributing to the solution of environmental problems.

Establishing of an in-situ information infrastructure represents significant added value in establishing a GMES-relevant capacity which requires the combination of remote sensing observations with in-situ measurements. Such combination facilitates the harmonization of methods for observing ecosystem variables and the networking of institutions performing observations related to ecosystems; advocates the development of tools to scale up from a limited number of in-situ ecosystem observations performed at local scales, to arrive at a large-scale, comprehensive picture of ecosystems; enables the validation of existing tools (such as synthetic aperture radar and hyperspectral imagers) for the measurement of ecosystem properties, advocates the

development of new sensors and platforms, and facilitate their use for routine observations on an operational basis.

The ground segment development focuses on the objective to progressively improve the deployment and operation of different thematic in-situ networks and surveys addressing cross-institutional and cross-national issues, such as assessment of sensitive areas for early warning and crisis management. Giving a general view of the ground segment of the information chain, stressing on the need for multidisciplinary research and multipurpose application and relying both on technology developments and data accuracy, this paper aims to initiate international joint research on test-sites as well as application activities, and to stimulate the cooperation between researchers and organizations in building and using multinational networks, developing integrated approaches and future collaboration. A main goal is to further enhance remote sensing capacities in treating and solving common problems. Networking is a useful instrument in international cooperation for knowledge and experience sharing. This paper can be considered as a partner search for the establishment of international collaboration and networking on test-sites in case of common research interests and problem solving.
